1. Scientific Principles: Natural Channel Design (NCD)

As a Geomorphology & Hydrologic Engineering Intern from Georgia Tech, you are responsible for translating physical stream surveys into stable, self-scouring channel geometries.
We utilize Dave Rosgen's **Natural Channel Design (NCD)** methodology. Degraded mountain streams are often in a state of high geomorphic instability, characterized by rapid lateral erosion (Type F or G channels) due to historic bank modifications. Our design goal is to transition these unstable reaches back to their stable historic geomorphic types (typically **Rosgen B or C channels** in montane ecoregions).
Your first task is to process field-collected cross-section, longitudinal profile, and substrate data to calculate the baseline and design geomorphic parameters.

---

2. Geomorphic Parameters and Core Equations

You will use the following standard equations to process stream survey spreadsheets:

```
                       STREAM CROSS-SECTION GEOMETRY

                            Floodprone Width (Wfp)
        |<------------------------------------------------------------------>|

                          Bankfull Width (Wbkf)
                          |<------------------>|

        ~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~  Floodprone Stage = 2 x Dmax
        --------------------|                  |------  Bankfull Stage (Dmax)
                            |   o   o.  o.  o  |
                            | o.  o.  o.  o.  o|
                            \__________________/
                               Stream Bed Sand/Cobble
```

A. Entrenchment Ratio (*ER*)

The entrenchment ratio measures the degree of vertical containment of a stream channel within its valley, representing the stream's access to its active floodplain.

$$ER = \frac{W_{fp}}{W_{bkf}}$$

Where:

- $W_{bkf} = \text{Bankfull Width (width of channel at bankfull water stage)}$.
- $W_{fp} = \text{Floodprone Width (width of valley at an elevation equal to twice the maximum bankfull depth, } 2 \cdot D_{max})$.
- *Classification*: Stable Rosgen B and C channels require $ER \ge 1.4$ (moderately to slightly entrenched). An $ER < 1.4$ indicates severe channel incision (incapable of flooding onto the valley flats, resulting in high shear stress and bank collapse).

B. Width-to-Depth Ratio (*WDR*)

The width-to-depth ratio indicates the channel's cross-sectional shape and is a primary indicator of sediment transport capacity.

$$WDR = \frac{W_{bkf}}{d_{mean}}$$

Where:

- $d_{mean} = \text{Mean bankfull depth } (A_{bkf} / W_{bkf})$, where A_{bkf} is the bankfull cross-sectional area.
- *Classification*: Stable high-gradient mountain streams (B-type) typically maintain a WDR between 12 and 20. An overwidened stream ($WDR > 25$) experiences a drop in shear stress, causing heavy silt deposition.

C. Sinuosity (*K*)

Sinuosity measures the degree of stream meandering.

$$K = \frac{L_{channel}}{L_{valley}}$$

Where:

- $L_{channel} = \text{Stream channel length measured along the thalweg (deepest point of flow)}$.
- $L_{valley} = \text{Straight-line valley length between the upstream and downstream points}$.

---

3. Step-by-Step Geomorphic Survey Processing

You will compile field-collected total station or RTK GPS coordinates to classify the stream reach:

Step 1: Process the Cross-Section Data

1. Open the survey CSV sheet containing *Station (x)* and *Elevation (y)* points across the channel cross-section.
2. Identify the **Bankfull Stage** elevation (marked by geomorphic indicators in the field, such as the top of flat depositional benches or changes in vegetation).
3. Calculate the bankfull area (A_{bkf}), bankfull width (W_{bkf}), and maximum depth (D_{max}) relative to this elevation.
4. Calculate $d_{mean} = A_{bkf} / W_{bkf}$.

Step 2: Process the Longitudinal Profile Data

1. Extract the elevation points along the channel thalweg, bankfull stage, and water surface over a length of at least 20 stream widths.
2. Calculate the average channel slope (S):

$$S = \frac{\text{Thalweg Elevation}_{up} - \text{Thalweg Elevation}_{down}}{\text{Stream Length}}$$

3. Identify pool-to-pool spacing and riffle slopes.

Step 3: Classify the Substrate (D_{50})

1. Plot the Wolman Pebble Count data as a cumulative percent finer curve.
2. Extract the $\boldsymbol{D_{50}}$ value (the particle size at which 50% of the substrate is finer).
3. If $D_{50} = 0.5\text{ mm}$, substrate is sand (Rosgen designation 5). If $D_{50} = 22\text{ mm}$, substrate is gravel (designation 4). If $D_{50} = 90\text{ mm}$, substrate is cobble (designation 3).

---

4. Geomorphic Rosgen Classification Lookup Matrix

Using the parameters calculated above, classify your stream reach according to the following lookup matrix:

Stream Type	Entrenchment Ratio (ER)	Width/Depth (WDR)	Sinuosity (K)	Slope (S)	Geomorphic Description
A	< 1.4 (Highly Entrenched)	< 12	$1.0\text{--}1.2$	> 0.04	Steep, entrenched, cascading step-pool stream.
B	$1.4\text{--}2.2$ (Moderately Entrenched)	> 12	> 1.2	$0.02\text{--}0.04$	Stable, rapids and rapids-dominated steps, low erosion risk.
C	> 2.2 (Slightly Entrenched)	> 12	> 1.2	< 0.02	Meandering pool-riffle channel with broad floodplain.
F	< 1.4 (Entrenched)	> 12 (Very Wide)	> 1.2	< 0.02	Highly unstable, entrenched, severely widening stream bend.
G	< 1.4 (Entrenched)	< 12 (Very Narrow)	> 1.2	$0.02\text{--}0.04$	Unstable "gully" channel with active severe bank slumping.

Restoration Goal: If a reach is classified as an eroding **F4** channel, your AutoCAD designs must narrower the bankfull channel and create a new floodplain bench to transition it to a stable **C4** or **B4** channel.
